

Size Effect on Plastic Deformation Behavior of Plain and Confined Concretes under Compression

中心圧縮を受けるプレーンおよびコンファインド コンクリートの塑性変形挙動における寸法効果

小池狭千朗・畑中重光*

Sachio KOIKE and Shigemitsu HATANAKA*

The purpose of the present study is to examine the effect of the specimen size and the aggregate size on the inelastic stress-strain behavior of both plain and confined concrete. The following statements can be drawn from the study.

- 1) It can be concluded that the behavior of the microconcrete in which the maximum size of coarse aggregate is reduced in proportion to the size of specimen may be more ductile than the concrete in actual structural members.
- 2) The behavior of confined concrete becomes more brittle with increasing size of specimen regardless of the spacing of hoops.

1. INTRODUCTION

Small scaled specimens are usually used for the test of Reinforced Concrete (RC) structures and members, because of the easiness of conducting experiments [1,2]. However, it is considered that there exists the effect of the size of a specimen on the strength and deformation properties of concrete [3,4]. To eliminate the size effect, microconcrete in which the size of aggregates is reduced in proportion to the size of a specimen is often used for the small scaled specimen[5,6]. It is, however, still questionable whether or not the size effect can be completely eliminated by using the microconcrete.

Little experimental data is available concerning the size effect on the stress-strain behavior of plain and confined concretes, while a lot of data exist

concerning the size effect on the compressive strength of plain concrete[7,8,9,10]. The purpose of the present study is to examine the effect of the specimen size and the aggregate size on the inelastic stress-strain behavior of both plain and confined concretes.

2. SIZE EFFECT OF PLAIN CONCRETE

2.1 Outline of experiment

The details of plain concrete specimens are shown in Table 1. The test variables include the sectional shape of a specimen (circle and square), the size of a specimen (prisms: $b \times b \times 3b$, $b=4.5, 5.6, 7.3, 9.7, 12.5, 15.0$ cm; cylinder: height(h)/diameter(d)=2; $d=7.5, 10, 15$ cm), the maximum size of aggregate ($\phi_a=5, 10, 20, 25, 30$ mm), and water-cement ratio ($W/C=45, 60, 70\%$). The number of specimens prepared for each combination of variables was 20, and the total number was 1800. Cylinders were cast vertically, prisms

were cast horizontally.

Ordinary Portland cement, river sand (maximum size: 5mm), and river gravel (size range: 5~30mm) were used for the fabrication of mortar and concrete. Slump was designed to be 15cm. All the specimens were stripped at the age of 3 days, and then cured in a room at a temperature of $20 \pm 2^\circ\text{C}$ and a relative humidity of $75 \pm 10\%$ until the tests. The tests were carried out at the age of 6 weeks.

The specimens were loaded under the constant strain rate of about $1 \times 10^{-3}/\text{min}$. up to the specified longitudinal strain (ϵ) of 10×10^{-3} by using a high rigidity compressive testing machine. The longitudinal strain was measured by a

couple of deformation transducers (measurement lengths were 2b for prisms and (h-2)cm for cylinders).

2.2 Test results and discussion

(1) Compressive strength

Figures 1 and 2 show the effect of the specimen size on the compressive strength (F_c) of prisms and cylinders, respectively. It is shown in these figures that i) the size effect of prisms and cylinders on the compressive strength is quite similar, i.e., the compressive strength increases with increasing specimen size (for the same maximum size of aggregate (ϕ_a)), and ii) the compressive strength decreases with increasing value of ϕ_a for the same size

Table 1 Details of plain concrete specimens

Size of prism	Size of cylinder	Water-cement ratio W/C (%)	Maximum size of aggregate ϕ_a (mm)
b×b×h (h=3b) (cm)	d*×h (h=2d) (cm)		
4.5×4.5×13.5	φ7.5×15	45	15, 25
5.6×5.6×16.8			
7.3×7.3×21.9	φ10×20	60	Mortar 10, 15, 20, 25, 30
9.7×9.7×29.1			
12.5×12.5×37.5	φ15×30	70	15, 25
15.0×15.0×45.0			

* d: diameter

Fig.1 Compressive strength of plain concrete versus section width of specimen (prism)

Fig.2 Compressive strength of plain concrete versus section diameter of specimen (cylinder)

of specimen. Note that all the specimens were cured in air.

Tanigawa et al.[9] reported, based on their test results, that the size effect in the compressive strength of concrete could be expressed by the product of the coefficient representing the effect in the compressive strength of mortar matrix and the other coefficient representing the effect of d/ϕ_a ratio (where, d : diameter of specimen, ϕ_a : maximum size of aggregate), i.e. the effect of geometrical heterogeneity. According to their proposed model reflecting the above findings, the compressive strength of concrete increases with the increase in the size of specimen for the value of d/ϕ_a smaller than about 8, and decreases with the increase in the size of specimen for the value of d/ϕ_a greater than about 8. In the tests conducted by Tanigawa et al., the specimens were cured in the room at a relative humidity of $90\pm 5\%$.

Morita et al.[10] conducted an experiment on the size effect of concrete using various sizes of cylindrical

specimens ($d=1.25\sim 15\text{cm}$) and coarse aggregates ($\phi_a=2.5\sim 10\text{mm}$). In their tests, it was found that the compressive strength of concrete was constant or increased with the increase in the size of specimen for the constant value of ϕ_a (where, $d/\phi_a=5\sim 60$). Those specimens were cured in water and tested in dry condition.

In the present experiment, the compressive strength of both mortar ($d/\phi_a=9\sim 30$) and concrete ($d/\phi_a=1.5\sim 15$) specimens increase with the increase in the size of specimen regardless of the value of d/ϕ_a . This tendency is different from the test results obtained by Tanigawa et al., and is similar to the results obtained by Morita et al., in spite of the fact that the curing conditions of concretes by the authors and Morita et al. are different.

Further experimental investigation is required for the effects of curing and testing conditions on the size effect, which are considered to affect the hydration of cement and drying shrinkage

Fig.3 Strain (ϵ_m) at maximum compressive stress of plain concrete versus section width of specimen (prism)

Fig.4 Strain (ϵ_m) at maximum compressive stress of plain concrete versus section diameter of specimen (cylinder)

of hardened concrete according to the specimen size.

(2) Strain at maximum compressive stress

Figures 3 and 4 show the effect of specimen size on the strain (ϵ_m) at maximum compressive stress of prisms and cylinders, respectively. Following statements can be drawn from the figures.

i) The size effects on the strain at maximum compressive stress observed for prisms and cylinders are very similar. As shown in Fig.3, the value of ϵ_m of concrete increases with increasing size of specimen for $b=4.5 \sim 9.7\text{cm}$, while it is almost constant for $b=9.7 \sim 15.0\text{cm}$. Quite similar tendency is observed in Fig.4.

ii) The value of ϵ_m of concrete decreases with increasing value of ϕa for the same size of specimen.

iii) The value of ϵ_m of mortar decreases with increasing size of specimen.

Morita et al.[10] reported that any significant effect of the specimen size ($d=1.25 \sim 15\text{cm}$) on the value of ϵ_m was not observed for the concrete of same mixture ($\phi a=2.5, 5$ or 10mm). Also, it was reported that in the microconcrete ($d/\phi a=5, d=1.25 \sim 15\text{cm}$), the value of ϵ_m became smaller with increasing size of specimen. In the result of the present experiment, any significant size effect on the value of ϵ_m was not observed for the

microconcrete (see Fig.7(a) to 7(c)).

(3) Stress-strain curve

Figure 5 shows the effect of specimen size on the stress(σ)-strain(ϵ) curve (hereinafter, $\sigma - \epsilon$ curve) of the prisms for $\phi a=25\text{mm}$. It is shown that the compressive strength and initial modulus of elasticity become larger, and the slope of stress descending portion becomes steeper with increasing size of specimen. The $\sigma - \epsilon$ curves converge at $\epsilon=(3 \sim 4) \times 10^{-3}$, which is similar tendency observed between the curves of concretes of different W/C or compressive strength.

Figure 6 shows the effect of the value of ϕa on $\sigma - \epsilon$ curve of the prisms of $b=7.3\text{cm}$. The compressive strength and the strain at maximum compressive stress become smaller, and the slope of stress descending portion becomes less steep to a small extent with increasing value of ϕa .

Figures 7(a) to 7(c) show comparisons of the $\sigma - \epsilon$ curves of concretes having almost same $b/\phi a$ ratio. The compressive strengths decrease and the descending portions of $\sigma - \epsilon$ curve show more ductile behavior for the smaller value of b or ϕa . Hence, it can be concluded that the microconcrete provides more ductile behavior than the concrete in actual structural members.

Fig.6 Stress-strain curve of prism of $b=7.3\text{cm}$

3. SIZE EFFECT OF CONFINED CONCRETE

3.1 Outline of experiment

The details of confined concrete are shown in Table 2. The test variables include the size of a specimen ($b \times b \times 3b$, $b=7.3, 9.7, 12.5, 15.0, 20.0\text{cm}$) and the spacing of hoops ($S=b/4, b/2, b, \infty$).

The size of specimens and the arrangement of hoops are schematically shown in Figs.8 and 9, respectively. Diameters of hoops were selected for the lateral reinforcement ratio (A_h/A_c , where, A_h : cross-sectional area of hoops, A_c : vertical cross-sectional area of specimen) to be approximately 0.3% in the case of the specimen with hoops of $S=b$. The number of specimen with hoops of $S=b$ for each combination of variables was 12, and the total number was 240. Water-cement ratio was set to 55%. The yield strengths of hoops used are shown in Table 3. Methods of fabrication, curing of specimen, and measurement of strain were the same as those of plain concrete

(a) $b/\phi a=4.5 \sim 5.0$

(b) $b/\phi a=6.5 \sim 7.5$

(c) $b/\phi a=8.3 \sim 10$

Fig.7 Comparison of stress-strain curve of concrete of almost same $b/\phi a$ ratio

Fig.8 Size of confined concrete specimen

Fig.9 Arrangement of hoop

Table 2 Details of confined concrete specimens

Size of prism		Hoop	
Section $b \times b$ (cm)	Height $h=3b$ (cm)	Diameter ϕ (mm)	Spacing S
7.3 × 7.3	21.9	3.2	b/4 b/2 b ∞
9.7 × 9.7	29.1	3.9	
12.5 × 12.5	37.5	4.9	
15.0 × 15.0	45.0	5.7	
20.0 × 20.0	60.0	8.0	

mentioned in Section 2.1. These specimens were loaded under the constant strain rate of about 2×10^{-3} /min. up to the specified strain ($\epsilon = 15 \times 10^{-3}$) in general.

3.2 Test results and discussion

(1) Compressive strength

Figure 10 shows the effect of specimen size on the compressive strength of confined concrete for various spacing of hoops. It is shown that, for plain concrete ($S = \infty$) and confined concrete with large spacing ($S = b$) of hoops, the compressive strength increases with increasing size of specimen, which is similar tendency observed for the plain concrete in Chap. 2. Such size effect, however, is not recognized for the confined concrete with small spacing ($S = b/4, b/2$) of hoops.

Table 3 Yield strength of hoop

Diameter of hoop (mm)	Yield strength (kgf/cm ²)
3.2	2415
3.9	2280
4.9	1937
5.7	2983
8.0	2654

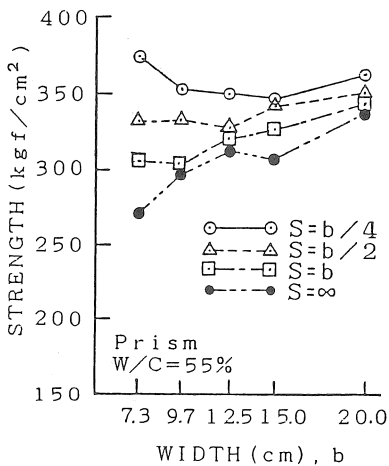

Fig.10 Compressive strength of confined concrete (prism)

(2) Strain at maximum compressive stress

Figure 11 shows the effect of specimen size on the strain (ϵ_m) at maximum compressive stress of the confined concrete for various spacing of hoops. It is shown that, for plain concrete ($S = \infty$) and confined concrete with large spacing ($S = b$) of hoops, the value of ϵ_m is hardly affected by the specimen size for $b > 9.7$ cm. For confined concrete with small spacing ($S = b/4, b/2$) of hoops, however, the value of ϵ_m decreases almost constantly with increasing size of specimen.

(3) Stress-strain curve

Figures 12(a) to 12(d) show the effect of specimen size on the $\sigma - \epsilon$ curve of confined concrete for various spacings of hoops. Here, damage of concrete

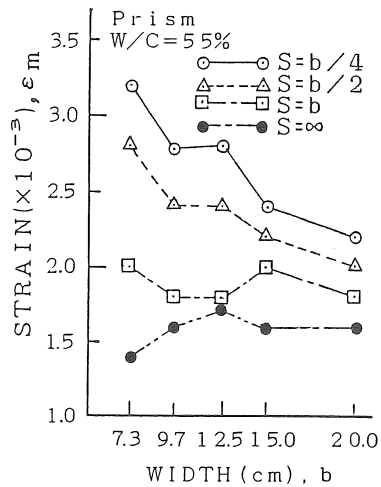

Fig.11 Strain(ϵ_m) at maximum compressive stress of confined concrete (prism)

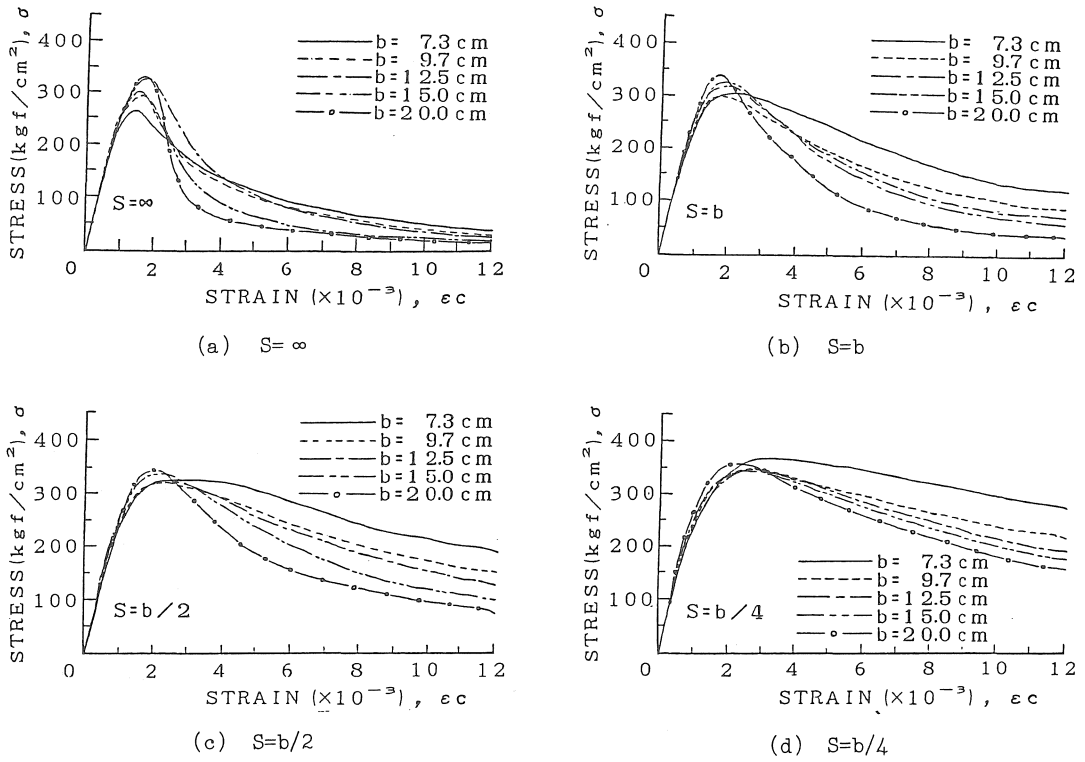

Fig.12 Effect of specimen size of stress-strain curve of confined concrete

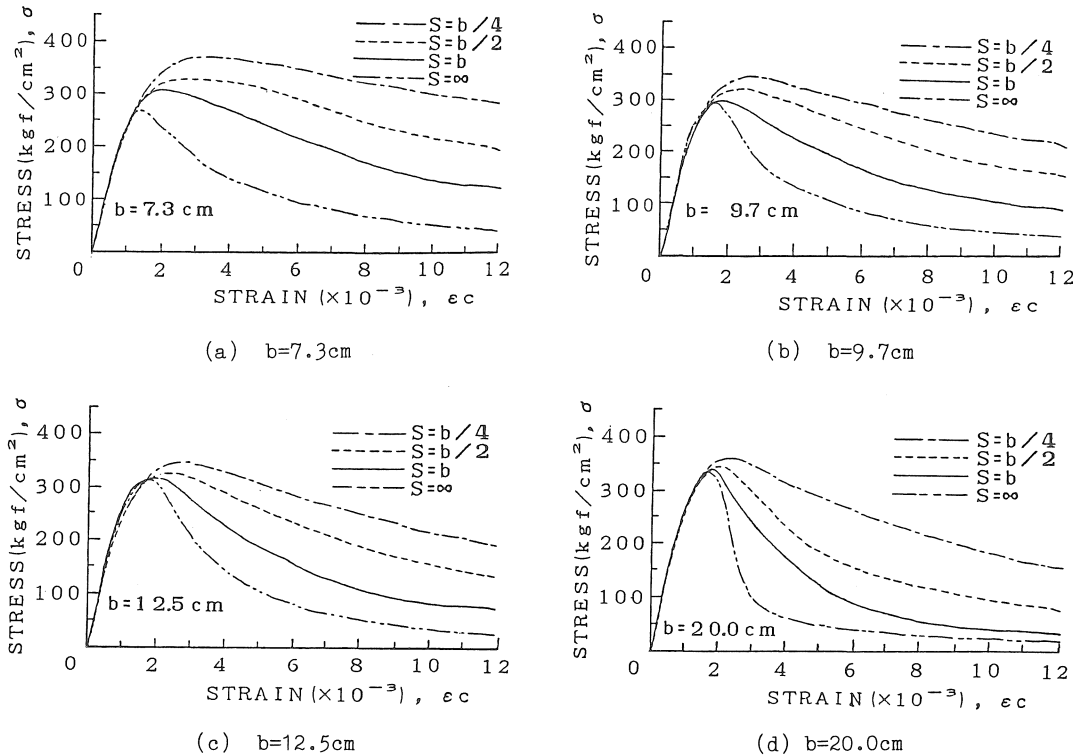

Fig.13 Effect of spacing of hoop on stress-strain curve of confined concrete

concentrated around the mid-height of specimens, so that all the damage concentrated zones were within the strain measurement region of specimens. The figures show that the descending portions of $\sigma - \epsilon$ curves become steeper with increasing size of specimen regardless of the spacing of hoops.

Figures 13(a) to 13(d) show the effect of spacing of hoops on the $\sigma - \epsilon$ curve of confined concrete for various sizes of specimen. Familiar tendency is observed that the compressive strength is higher and the descending portion of $\sigma - \epsilon$ curve is less steep for the smaller spacing of hoops. Note that this tendency is more remarkable for the smaller specimens.

4. CONCLUSION

The effect of the size of specimens and aggregates on the deformation behavior of plain and confined concretes was discussed. The following statements can be drawn from the study.

1) For plain concrete, stress (σ)-strain (ϵ) curves are quite different between microconcretes in which the maximum size of coarse aggregate is reduced in proportion to the size of specimen. Namely, the compressive strength decreases and the descending portion of $\sigma - \epsilon$ curve shows more ductile behavior with decreasing size of specimen or aggregate (Fig.7(a) to 7(c)). Hence, it can be concluded that the behavior of the microconcrete may be more ductile than the concrete in actual structural members.

2) The compressive strength of confined concrete increases with increasing size of specimen for large spacing of hoops. Such size effect, however, is not recognized for small spacing of hoops (Fig.10).

3) The behavior of confined concrete becomes more brittle with increasing size of specimen regardless of the spacing of

hoops (Fig.12(a) to 12(d)).
